

# Introduction to High-Performance Computing

Session 07  
Performance Optimization

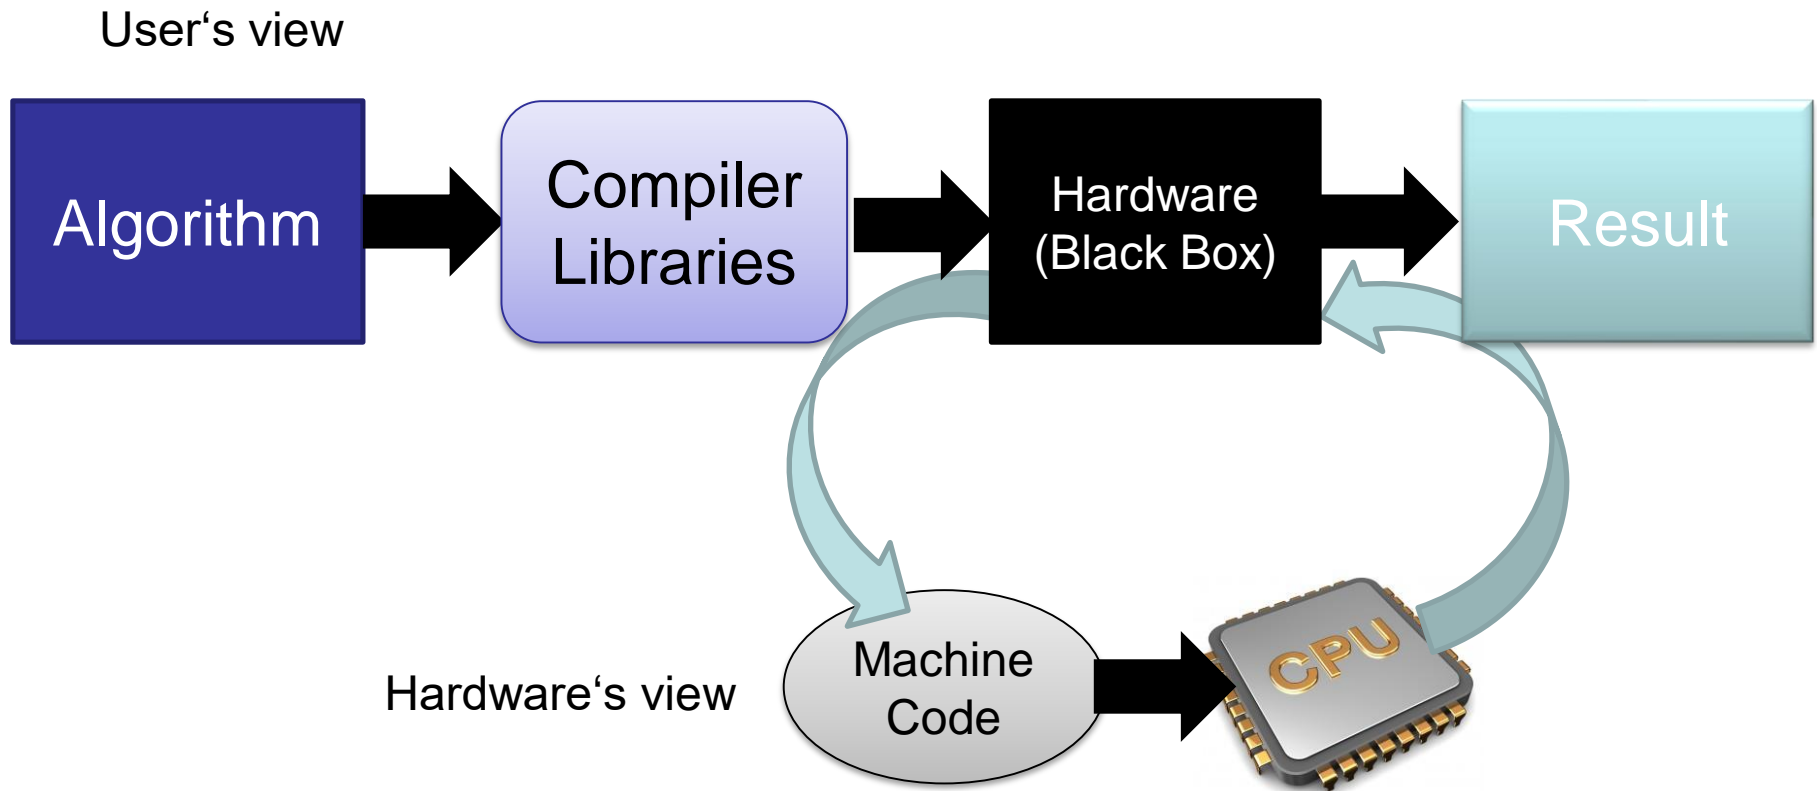

# Performance Modelling

- the following slides are based on

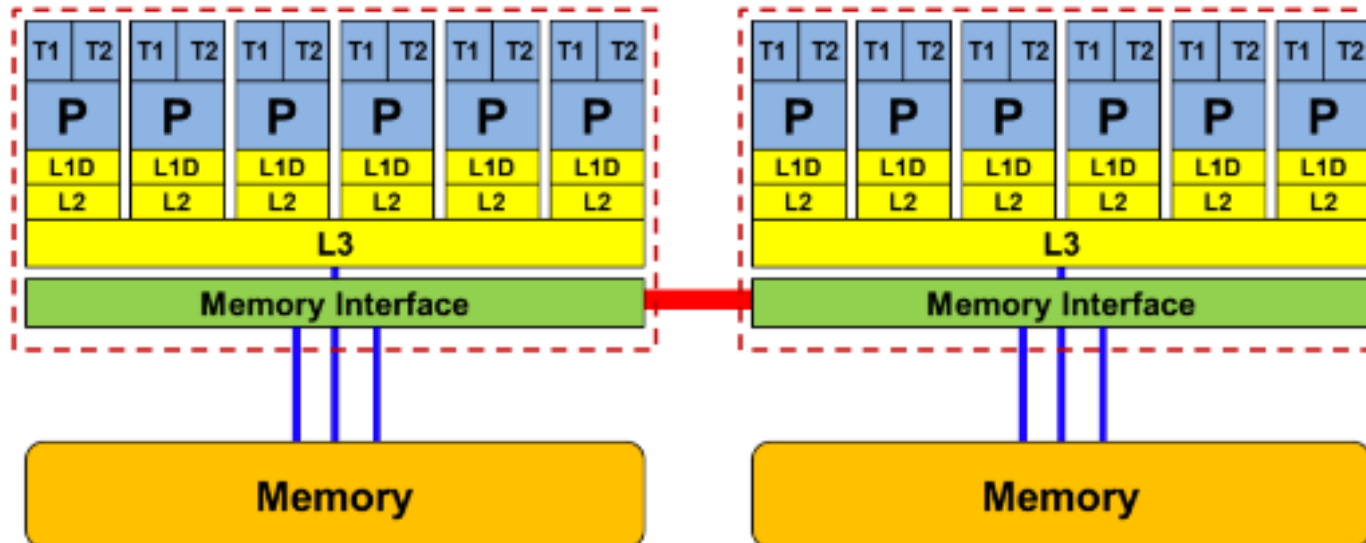

<http://moodle.rrze.uni-erlangen.de/course/view.php?id=311&username=guest&password=guest>

- 2-day course during MCS Summer School 2014 given by Georg Hager
- Book: G. Hager and G. Wellein:  
**Introduction to High Performance Computing for Scientists and Engineers,**  
CRC Computational Science Series, 2010. ISBN 978-1439811924  
<http://www.hpc.rrze.uni-erlangen.de/HPC4SE/>

# Computer Software and Hardware

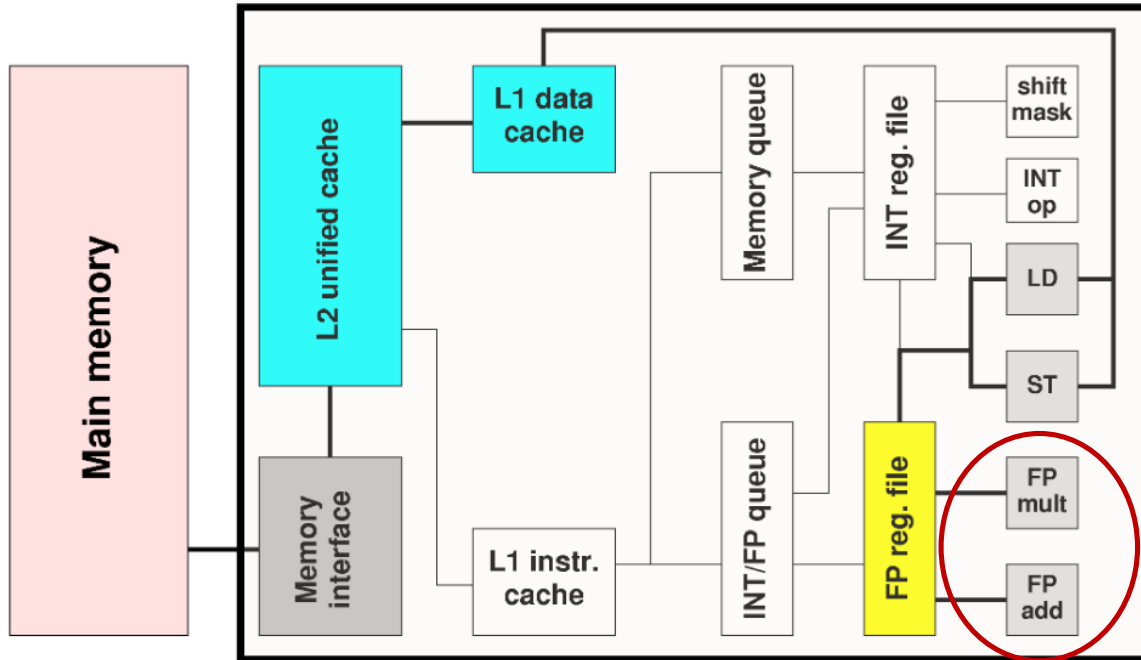

# Modern Computer Architecture

- today: dual-socket node
  - multiple cores per socket/CPU
  - ccNUMA architecture
  - socket interconnect

# Detailed View Compute Core

## Execution Units Broadwell

- two EUs for FP instructions

- each EU can execute one FP instruction at a time

Not shown: most of the control unit, e.g. instruction fetch/decode, branch prediction,...

execution units  
(shown only for FP)

## Example: Divide Throughput

- in the `Pi.cpp` code the function  $f(x)$  has one division

```
// define f so that integral of f from 0 to 1 is Pi
double f(const double x) {
    return (4.0/(1.0+x*x));
}
```

- division is the dominant operation (other instructions can be hidden)
- for  $n$  evaluations of  $f$  we get  $t = n \cdot \frac{c}{\nu}$
- Broadwell CPUs need  $c = 5$  cycles/division (throughput) and assuming turbo mode (clock speed  $\nu = 2.5\text{GHz}$ ) we would expect  $t = 0.2\text{s}$  for  $n = 10^8$

## Execution of Instructions

- programmer's view:

```
for (int i=0; i<N; i++)  
    A[i] = A[i] + B[i];
```

- user work:  
N Flops (ADDs)

- hardware's view:

```
load r1 = A(i)  
load r2 = B(i)  
add r1 = r1 + r2  
store A(i) = r1  
inc i  
branch top if i<N
```

programm performs computation, FLOP is the basic work done  
processor executes instructions, instructions is the basic work done

# Basic Compute Resources

- instruction execution
  - primary resource for computations, hardware is designed to increase instruction throughput as much as possible
  - difficult for general purpose computing, what is a typical workload?
- data movement
  - consequence of instruction execution
  - in the example two loads and one store (double 24 byte)

**What is the bottleneck of an application?**

## Flop/s vs. Memory Bandwidth

- a floating-point operation (Flop) is the basic unit of work
  - theoretical peak performance Intel Xeon E5-2650 v4

$$P_{\text{peak}} = 422.5 \text{ GFlop/s}$$

- equivalent to  $16 \text{ Flop}/(\text{core} \cdot \text{cy})$
- memory bandwidth
  - maximum for Intel Xeon E5-2650 v4 is  $76.8 \text{ GB/s}$   
([https://ark.intel.com/products/91767/Intel-Xeon-Processor-E5-2650-v4-30M-Cache-2\\_20-GHz](https://ark.intel.com/products/91767/Intel-Xeon-Processor-E5-2650-v4-30M-Cache-2_20-GHz))
  - equivalent to  $35 \text{ Byte/cy}$

(more info: <http://sites.utexas.edu/jdm4372/tag/memory-bandwidth/>)

## Example Bandwidth Limited Execution

- consider the vector-triad

```
for (j=0; j<STREAM_ARRAY_SIZE; j++)  
    a[j] = b[j]+scalar*c[j];
```

- included in the STREAM benchmark (see <https://www.cs.virginia.edu/stream/>)
- 2 Flop/iteration and 24 Byte/iteration
- at 16 Flop/cy on a single core 192 Byte/cy are needed

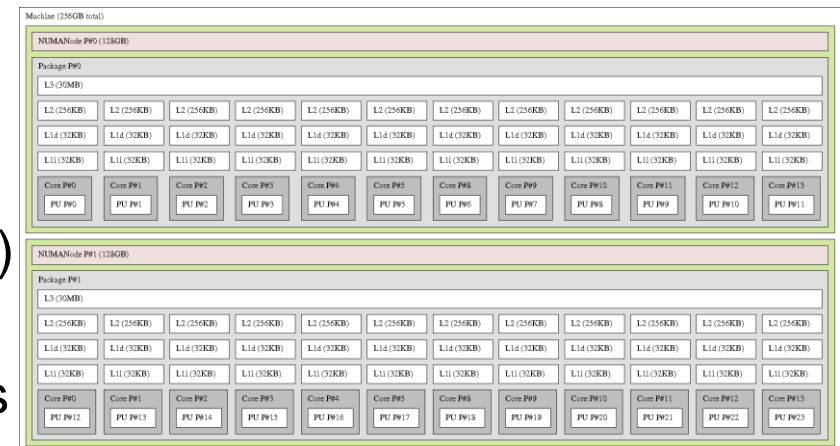

→ memory bandwidth is the limiting factor here

# Hardware Locality

- compute nodes are increasingly complex
  - ccNUMA architectures
- the `hwloc` library provides some tools to

(<https://www.open-mpi.org/projects/hwloc/>)

- obtain information about the node topology (`lstopo`)
- bind processes to specific cores/sockets/...
- binding/pinning of threads may improve performance (`hwloc-bind ... <command>`)
- difficult to decide, e.g. is it better to use neighboring cores or different sockets?

# STREAM Benchmark

<https://www.cs.virginia.edu/stream/>

- simple tool to measure memory bandwidth
  - timing of bandwidth-limited vector operations
- some results
  - single core bandwidth is about 20 GB/s
  - maximum bandwidth measured is about 64 GB/s per socket and 128 GB/s per node (two sockets)
  - about half of the cores are need to get (close to) maximum bandwidth

## Example

- 3d „Stencil“ update (Jacobi)

```
// serial
for (int i=1; i<Ni; i++)
  for (int j=1; j<Nj; j++)
    for (int k=1; k<Nk; k++)
      y[i][j][k] = w * ( x[i-1][j][k] + x[i+1][j][k]
                        + x[i][j-1][k] + x[i][j+1][k]
                        + x[i][j][k-1] + x[i][j][k+1] );
```

note that the order of the loops is important  
(and depends on the ordering of multi-dimensional arrays in memory)

# Memory Access Patterns

- **Caches help with getting instructions and data to the CPU “fast”**
- **How does data travel from memory to the CPU and back?**
- Remember: Caches are organized in **cache lines** (e.g., 64 bytes)
- Only **complete cache lines** are transferred between memory hierarchy levels (except registers)
- **MISS**: Load or store instruction does not find the data in a cache level → CL transfer required
- Example: Array copy  $A(:) = C(:)$

# Parallel Speedup

version 1, very good scaling  
version 2, almost no scaling

performance of version 2 is  
better by factor of few

# Parallel Performance

bandwidth limit  
 $\cong$  48 Byte/iter  
 $\cong$  9.6 GFlop/s

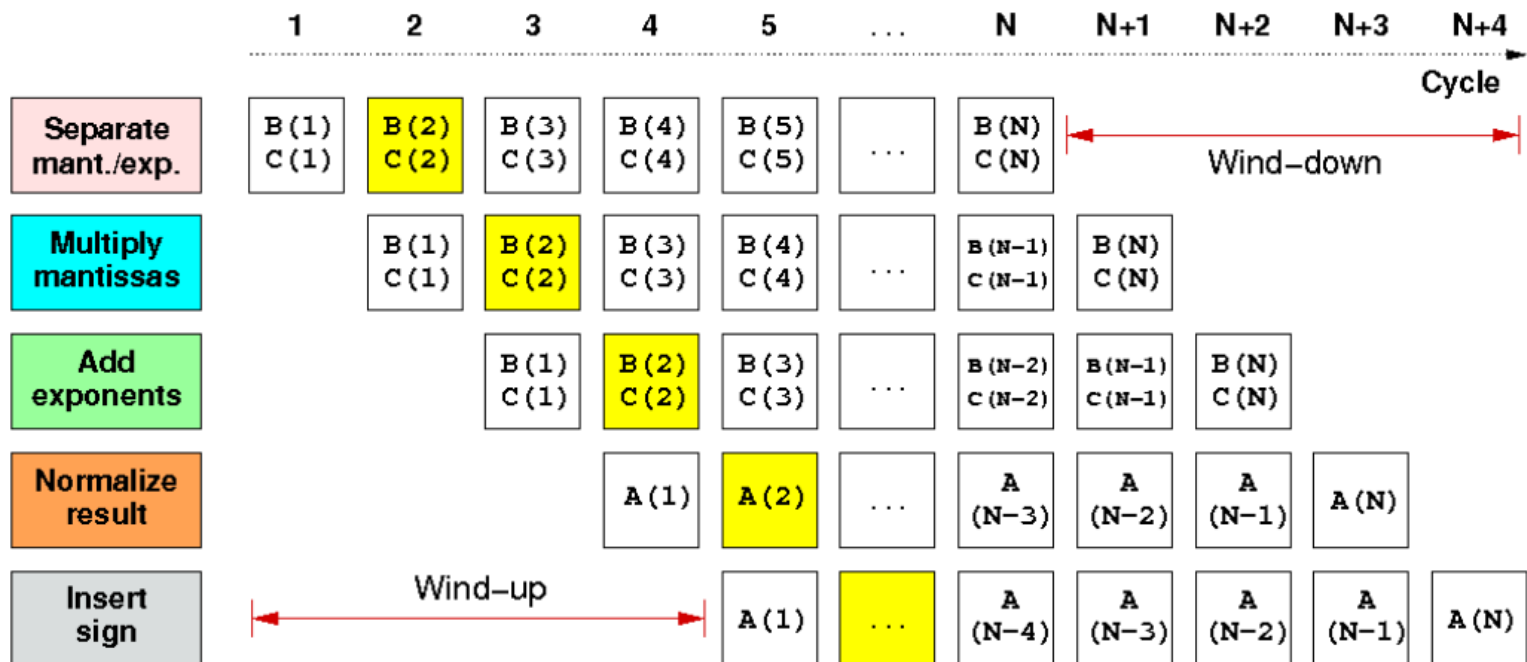

## How is the Hardware optimized for performance?

- speedup memory access with cache (see before)
- pipelining of arithmetic units
- instruction pipeline
- instruction level parallelism
- simultaneous multi-threading (SMT)
- SIMD processing

# Pipelining

- **Idea:**
  - Split complex instruction into several simple / fast steps (stages)
  - Each step takes the same amount of time, e.g., a single cycle
  - Execute different steps on different instructions at the same time (in parallel)
- **Allows for shorter cycle times (simpler logic circuits), e.g.:**
  - floating point multiplication takes 5 cycles, but
  - processor can work on 5 different multiplications simultaneously
  - one result at each cycle after the pipeline is full
- **Drawback:**
  - Pipeline must be filled - startup times ( $\#Instructions \gg$  pipeline steps)
  - Efficient use of pipelines requires large number of independent instructions → instruction level parallelism
  - Requires complex instruction scheduling by compiler/hardware – software-pipelining / out-of-order
- **Pipelining is widely used in modern computer architectures**

# Pipelining – 5 stage Multiplication

First result is available after 5 cycles (=latency of pipeline)!

Wind-up/-down phases: Empty pipeline stages

# simultaneous multi-threading (SMT)

SMT principle (2-way example):

# SIMD processing

- **Single Instruction Multiple Data (SIMD)** operations allow the **concurrent execution of the same operation on “wide” registers**
- **x86 SIMD instruction sets:**
  - SSE: register width = 128 Bit → 2 double precision floating point operands
  - AVX: register width = 256 Bit → 4 double precision floating point operands
- **Adding two registers holding double precision floating point operands**

# Processor Peak Performance

Intel Xeon „Broadwell“  
 E5-2650 v4

TOP500 rank 1 (mid-90s)

## Floating Point (FP) Performance:

$$P = n_{\text{core}} \cdot F \cdot S \cdot \nu$$

$n_{\text{core}}$	number of cores	12
$F$	FP instructions per cycle (2 FMA)	4
$S$	FP ops / instruction (256 Bit SIMD registers in AVX2)	4
$\nu$	clock speed (affected by turbo/AVX modes)	2.2 GHz

---

$$P = 422.4 \text{ GFlop/s (dp)}$$

**But:  $P = 8.8 \text{ GFlop/s}$  for serial, non-SIMD code**

## Performance Bottleneck

- many floating point computation on little data
  - bound by the processing speed of the CPU
    - possibly increase number of cores
    - make use of SIMD processing
    - note: recent CPU may have lower clock speed for AVX
- few floating point operation per data
  - bound by memory bandwidth
    - change algorithm/parallelization to make better use of cache
    - increase compute intensity

## Examples

- OMP\_Pi
  - how many CPU cycles are required for a DIV operation?
- STREAM
  - determine memory bandwidth
- Stencil
  - optimization vs. speedup
  - memory access pattern

measuring/getting optimal performance may require  
process binding
